#### Abstract

\title{ Congruency Effects with Dynamic Auditory Stimuli }

by

Bruce N. Walker

As auditory displays become more common it is increasingly important to understand the perception of complex and dynamic auditory stimuli and how the information contained in the various dimensions of these stimuli influences performance. In the present study listeners made keypress responses to dynamic sound stimuli which started high or low in pitch and became higher or lower in pitch during each trial. The results showed that pitch and pitch change interacted in an asymmetrical manner, with pitch information intruding more on judgments of pitch change than vice versa. Neither pitch nor pitch change interacted with vertically arranged responses to produce the strong spatial S-R compatibility effects that were expected based on previous research and on descriptions of pitch in everyday language. Analytic versus holistic listening strategies or the physical location of the sounds may affect interactions of the stimuli and responses in this type of selective listening task.

## INTRODUCTION

Performing many types of tasks in a variety of real-world settings requires selective attention to just one dimension of a stimulus. For example, in order to avoid a collision a pilot might need to make a speeded response based on the proximity of an oncoming plane, ignoring, for the moment at least, the size or color of it. The increasing use of auditory displays means that a growing number of professionals, from pilots, to surgeons, to control room engineers, must rely on sounds emitted in their environment, by their tools and even from communications devices to guide their actions. In order to design auditory interfaces which afford better comprehension and elicit faster and more accurate reactions, one must first understand how different attributes of auditory stimuli interact to influence perception and responding. One major question is whether it is possible to attend selectively to a given dimension of a sound, while ignoring other dimensions of the sound. For example, a Geiger counter operator may need to listen specifically to the temporal pattern of the sound, which indicates the prevalence of radioactive particles, and ignore changes in the pitch of the sound, which may indicate the type of particles that are present. On the other hand, in monitoring a landing approach an air traffic controller may need to attend to the rate of pitch change that represents rate of descent of an airplane, while paying less attention to the absolute pitch of the sound, which represents the actual altitude of the plane.

Design of any sort of control apparatus also requires an understanding of how the displayed stimulus features interact with the attributes of the response set. For example, it has been shown that when using left and right buttons to respond to a light which may appear on the left or on the right side of a display, faster responses result when the left light is paired with the left button and the right light is paired with the right button, rather than the opposite assignment of lights to buttons (e.g., Proctor \& Reeve, 1990). Simple
high-pitched sounds may also afford faster responding than low-pitched sounds, if the response is an upward motion of a switch. This high-pitch advantage for upward responses may not apply for other response devices, such as the left and right buttons mentioned in the previous example, or for stimuli that do not remain constant. In addition, the influence of pitch on responding may depend on how the other attributes of the sound, such as its tempo, timbre or loudness, are related to the response set.

## Stimulus-Stimulus Interactions

When the correctness of a response depends on selectively attending to one dimension of a sound, and ignoring the other stimulus dimensions, performance will depend on how the individual dimensions of the sound are perceived and how different dimensions combine to influence performance. Of the various attributes of sound that may be used to display information, pitch is of primary interest because it is the dimension most commonly used to represent data in auditory displays. In particular, it is important to know how pitch interacts with dynamic changes in the stimulus (including changes in pitch itself) because the auditory representation of data rarely involves single, static values (i.e., unchanging pitches). For this reason, it is important to understand how pitch is perceived, how pitch interacts with other stimulus dimensions to affect responding in selective listening tasks and how these interactions affect responses to dynamic auditory stimuli.

The present research explores the effects of pitch change on pitch classification, as well as the effects of relative pitch on the classification of pitch change. In addition this research examines some of the effects of the nature of the response set and the assignment of particular stimuli to particular responses.

Pitch perception. The perception of pitch has been studied extensively. There is a wealth of research exploring the physics of sound and the mechanisms of hearing (e.g., Moore, 1989), the psychophysical aspects of perception and discrimination of different
pitches (e.g., Bregman, 1990; Moore, 1989; Stevens, 1957), how pitch fits into the structure of music (e.g., Révész, 1954) and the psychological aspects of hearing, pitch and music perception (e.g., Deutsch, 1982). Pitch is often used as a dimension in auditory displays for the very reason that so much is already known about simple pitch perception. In addition, most listeners are familiar with the concept of pitch and can detect fairly small pitch changes with little training (e.g., $1-\mathrm{Hz}$ change in a pure tone of 1000 Hz ; Moore, 1989). Another reason for using pitch as a display dimension is the relative ease with which pitch can be controlled by current display hardware (Kramer, 1994). Pitch also more evenly represents a wider range of values than, say, loudness, since at the extremes loudness does not provide an effective display dimension (as soft sounds are masked by ambient noise, and loud sounds are potentially disturbing or even damaging).

Pitch in interaction with other dimensions. Relatively little is known about how pitch interacts with other stimulus dimensions and how successful listeners can be at attending to just one of several auditory stimulus dimensions. For many pairs of stimulus dimensions subjects are able to respond solely on the basis of the information contained in the relevant or "cue" dimension, and successfully ignore the other, "irrelevant" dimension. However, for other pairs subjects are not able to attend selectively to one dimension. Rather, performance is disrupted by variations in the other dimension. An example of how pitch can affect perception of another stimulus dimension is Melara and Marks' (1990) finding that listeners responded faster to a loud sound if the sound was also high, rather than low in pitch-despite instructions to ignore the pitch. Correspondingly, responses to soft sounds were faster if the pitch was low, rather than high. Other studies have demonstrated interactions of pitch with other auditory dimensions, including loudness (e.g., Grau \& Kemler Nelson, 1988; Marks, 1982; Melara, Marks \& Lesko, 1992; Stevens, 1935), timbre (e.g., Melara \& Marks, 1990), waveform and duration (e.g., Walker, 1987) and the physical location of the sound (e.g., Simon and Rudell, 1967).

Cross-modality matching studies have demonstrated that pitch also interacts with some non-auditory stimulus dimensions including the brightness of lights (high $\leftrightarrow$ bright), the brightness of colors (high $\leftrightarrow$ white), the "sharpness" of shapes (high $\leftrightarrow$ sharp; Marks, 1987), and the spatial location of a visual object (high pitch $\leftrightarrow$ high location of a visual target; Melara \& O'Brien, 1990).

Dynamic stimuli and congruency effects. To date, virtually all of the research on interactions of pitch with other stimulus dimensions has involved an unchanging pitch and another static stimulus dimension. Thus, there is still much to be learned about dynamic auditory stimuli, and, in particular, about how changing pitch plays a role in perceiving and making responses to other aspects of a sound. Recent findings with dynamic visual stimuli suggest that changes within a stimulus dimension may interact with responding to a given value of that same stimulus dimension. For instance, it has been shown that perception of the physical position of a visual target is influenced by the direction of motion of the target, even when the task is to respond to, for example, onset position and ignore the motion of the target (e.g., Ehrenstein, 1994; Michaels, 1988; 1993; Proctor, Van Zandt, Lu \& Weeks, 1993). In the case where the task is to attend selectively to the onset position of a visual target (i.e., whether a square appears on the left or the right side of the display), responses are typically faster if the position (e.g., left) is congruent with the direction of motion of the same visual target (e.g., the square moves farther to the left). Responses are slower if the position and direction of movement are incongruent (i.e., the square appears on the left, but moves toward the right side of the display; Ehrenstein, 1994; Proctor et al., 1993). It remains to be seen whether, in the auditory domain, the interaction of pitch and pitch change produce similar congruency effects, so that if a sound is high in pitch, responding is faster if the sound becomes higher in pitch than if it becomes lower in pitch, and vice versa.

## Stimulus-Response Interactions

In addition to studying how one attribute of an auditory stimulus affects perception of another attribute of the same (or different) stimulus, much research has been conducted in an attempt to understand how the information contained in a stimulus dimension affects the selection of an appropriate response to that information. Research has shown that different assignments of stimuli to responses can result in different performance for a task. Although most studies in this area have considered the stimulusresponse (S-R) assignment for one dimension of the stimulus, it has also been found that the correspondence between a second, irrelevant dimension (i.e., one that was supposed to be ignored) and the response set can affect response time and accuracy, depending on how the irrelevant dimension is related to the response set. The following sections discuss some of the effects that can result from different assignments of either taskrelevant or task-irrelevant stimulus dimensions to responses.

Stimulus-response compatibility effects. In general, S-R compatibility effects refer to the differences in reaction time (RT) and accuracy obtained under different assignments of a single dimension of a stimulus to the allowable responses in a task (e.g., Fitts \& Seeger, 1953; Proctor \& Reeve, 1990; see also Simon, 1990). These effects are described as spatial compatibility effects when they arise as a result of the correspondence of a spatial attribute of the stimulus to spatially arranged responses (e.g., Fitts \& Deininger, 1954; Fitts \& Seeger, 1953; Proctor \& Reeve, 1990). For example, if the task is to press one of two vertically arranged response keys when one of two vertically arranged lights is turned on, responses will be faster if the upper light is assigned to the upper key, and the lower light is assigned to the lower key (the compatible S-R assignment), than when the upper light is assigned to the lower key and the lower light is assigned to the upper key (the incompatible assignment; see Proctor \& Reeve, 1990, for an overview). Spatial compatibility effects have also been found for auditory stimuli. For example, the spatial location of a sound (i.e., whether it is presented
via the upper or lower of two speakers) can interact with vertically arranged responses, such that keypresses are faster if the response is to press the upper key when a sound is presented from the upper speaker, compared to when the response is to press the upper key when the sound is presented from the lower speaker (Simon \& Craft, 1970). The S-R assignments that result in faster performance in these cases are considered "compatible", whereas the S-R assignments that result in slower performance are considered "incompatible".

Pitch has also been found to result in spatial compatibility effects, in that assigning high pitch to an upper (or upward) response (the compatible assignment) results in faster responding than assigning high pitch to a lower (or downward) response (the incompatible assignment; Simon, Mewaldt, Acosta, \& Hu, 1976).

While it was not a study of S-R compatibility effects, per se, Mudd (1963) also found evidence that there are population stereotypes involved in listening and responding to pitch. In his study subjects listened to pairs of sounds, then placed pegs on a pegboard to represent the relative spatial locations that the sounds connoted. Listeners tended to place pegs higher up in the pegboard in response to higher pitched sounds. Thus, it appears from Mudd's experiment that listeners treated pitch as being correlated with vertical spatial position.

Compatibility effects from to-be-ignored dimensions. Although the majority of S$R$ compatibility studies have featured spatial attributes of stimuli assigned to spatial response sets, Simon and his colleagues have shown that compatibility effects can also arise from correspondences between the response set and stimulus dimensions that are nominally irrelevant to the task (e.g., Simon, 1990; Simon \& Rudell, 1967; see Lu \& Proctor, 1995 for a review). For example, if the task is to respond with a left key when the spoken word "left" is heard, and to respond with a right key when the word "right" is heard, while ignoring the ear in which the word is presented, it turns out that the to-beignored spatial location of the stimulus (i.e., in which ear the stimulus is presented)
affects response time and accuracy. In particular, when the spatial location of the stimulus corresponds to the location of the correct response (based on the relevant cue dimension), responding is faster than if the (supposedly irrelevant) spatial location of the stimulus is opposite to the location of the correct response.

Although first described in a paradigm using spoken words and spatially arranged responses (Simon \& Rudell, 1967), such effects of irrelevant stimulus dimensions (commonly called the Simon effect) are not limited to auditory stimuli. Similar effects have also been found using visual and cross-modal stimulus dimensions. For example, Craft and Simon (1970) presented red and green lights to the left and right eyes, and instructed subjects to respond to a red light with a right-hand button, and respond to a green light with a left-hand button without regard for where the stimulus was presented. Responses to the red stimulus were faster when it was presented to the right eye than when it was presented to the left eye. Likewise, responses were faster for a green stimulus when it was presented to the left eye. Thus, the task-irrelevant spatial position of the stimulus influenced responding to the task-relevant color of the stimulus (see also Hedge \& Marsh, 1975; Proctor \& Lu, 1994; Umiltà \& Nicoletti, 1985). As an example of cross-modal stimulus interaction, Simon and Craft (1970) presented lights to the left or right of fixation, accompanied by high or low-pitched tones presented to the left or right ears. The ear of presentation for the tone was irrelevant to the task, yet responses were faster when the ear of presentation matched the stimulus presentation side.

Although nearly all of the work on the Simon effect with auditory stimuli has used the left-right spatial distinction, Simon et al. (1976) examined the effects of vertical spatial location (i.e., the speaker from which the sound was presented, which was irrelevant to the task in this case) on responses to the pitch of a stimulus. As is the case when left and right spatial locations affect performance even though nominally irrelevant to the task, Simon et al. found a strong effect of the irrelevant spatial information on reactions to pitch (when high and low pitches were compatibly assigned to high and low
responses). When the high pitch stimulus (i.e., high in terms of pitch, not in terms of vertical position) was paired with an upward toggle response, and the low pitched stimulus with a downward toggle response (i.e., in a compatible assignment of the relevant stimulus dimension to the responses), responses were significantly faster when the high pitches emanated from the upper speaker, rather than from the lower speaker. In other words, when the irrelevant spatial dimension of the stimulus (i.e., upper vs. lower speaker) was spatially compatible with the correct response, responses were faster than when the spatial location of the sound and the response did not correspond.

Dynamic stimuli and compatibility effects. Some of the studies that looked at congruency effects with dynamic visual stimuli also examined S-R compatibility effects, in particular the effect of the compatibility of task-irrelevant spatial information (e.g., Ehrenstein, 1994). Compatibility effects with dynamic auditory stimuli have yet to be studied. However, if auditory stimuli that change in pitch can be considered dynamic in that they move up or down in the so-called "pitch space", and if the responses to such stimuli are arranged vertically, then S-R compatibility effects should be observed. A Simon effect for such dynamic auditory stimuli might also be expected, if the position and movement of a sound in the pitch space affect responses to other attributes of the stimulus even when they are irrelevant to a selective listening task. It should be noted that sounds can be made dynamic in several other ways, including moving them in space around the listener (via phase shifts for simple left-right motion, or via three-dimensional convolution; e.g., Wenzel, Arruda, Kistler, \& Wightman, 1993). Such dynamic auditory stimuli may also result in S-R compatibility effects. However, since sounds that change in pitch are important for the auditory display of information, the present study focused on stimuli that are dynamic in the pitch space.

If it is possible to attend selectively to the onset pitch of a stimulus while ignoring the direction of pitch change, then the time it takes to judge whether a tone is high or low in pitch, and the accuracy of this judgment, should not depend on pitch change. That is, whether a high pitch becomes lower or higher in pitch and a low pitch becomes lower or higher in pitch should not affect performance. However, if the pitch-change information intrudes on the pitch decision, the speed and accuracy of responses to high pitches that become higher and to low pitches that become lower should be better than for responses to high pitches that become lower and low pitches that become higher. This is because the high pitches that become higher and the low pitches that become lower provide congruent information to the listener, in that the pitch change makes the stimulus "more" of what it already is, namely "high" or "low" in pitch. The high pitches that become lower and the low pitches that become higher provide conflicting, or incongruent information to the listener, which should result in performance deficits for responses to those stimuli. Similar arguments could be made for the effects of onset pitch on judgments of pitch change. For example, a tone that becomes higher in pitch, and that starts at an already high pitch, is never "low", so it provides congruent information to the listener. A tone that is becoming higher in pitch, but is initially "low" provides incongruent information to the listener, and this may necessitate more or different processing of the stimulus. Responses to the congruent stimuli will likely be faster than responses to the incongruent stimuli.

To investigate interactions between the dimensions of pitch and pitch change, sounds that started at a given pitch, and then became higher in pitch (i.e., changed to a higher frequency), or became lower in pitch (i.e., changed to a lower frequency) were presented. Subjects were instructed to listen to the sounds, attending selectively either to the pitch or to the direction of pitch change, and then make a speeded classification
according to whether the pitch was high or low, or becoming higher or lower, respectively.

The experiment used a set of 12 stimuli, each of which became higher or became lower in pitch from one of several starting pitches (see Figure 1). The use of a large stimulus set helped avoid any problems that might otherwise result if there were peculiarities in responding to specific pitches or pitch changes. On the basis of pilot testing, it seemed necessary to use a relatively large set of stimuli to prevent subjects from learning to associate a particular response with a given stimulus, and to encourage participants to listen analytically to either the onset pitch or direction of pitch change.

## Method

Participants. Twenty-eight Rice University undergraduates each participated in a one-hour experiment for partial credit in a psychology course. All subjects reported normal hearing, and none had participated in the pilot studies. Subjects were assigned randomly to conditions, with the constraint that there were equal numbers of subjects in each condition.

Apparatus. Subjects were tested individually in a small testing room, at a table with an IBM-compatible 486-DX 33-MHz computer, 14-in. color VGA monitor and standard 101-key keyboard. A program written in MEL (Micro Experimental Laboratory; Schneider, 1988; 1995) controlled stimulus presentation and data collection. Auditory stimuli were presented by the computer's internal speaker, centrally located with respect to the subject. Responses were made using the " 6 " and " 9 " keys on the numeric keypad with their right index and middle fingers, respectively. Due to the tilt of the keyboard, the " 9 " key was slightly above the " 6 " key (and slightly further from the subject), for a quasi-vertical arrangement of responses.

Stimuli. The stimuli were brief pitch glides composed of a series of short pitches (see Figure 1 and Appendix A for the initial and final frequencies of the stimuli). The
duration of each sound was 250 ms , with 10 intermediate steps creating an apparently continuous change in pitch. The changes in the stimulus pitch were made equal in terms of $\log$ frequency in order to equate the change in perceived pitch for all stimuli.

FIGURE 1. Schematic representation of the 12 auditory stimuli. The circle represents the starting pitch, and the arrow indicates the direction of pitch change, with the final pitch at the tip of the arrow. Note that the vertical axis is log frequency; thus, the equal arrow lengths reflect equal changes in perceived pitch for each stimulus. The initial and final frequencies are summarized in Appendix A. The horizontal line in the figure represents the relative "middle" of this pitch space: Stimuli that started above this frequency were considered relatively "high" in pitch and the others were considered relatively "low" in pitch. The stimuli are also labeled in terms of their separation, or relative distance from the middle of the stimulus set.

Stimuli for which the sound started high and became higher or started low and became lower in pitch were considered "congruent", since their onset position and direction of pitch change corresponded (the left stimulus in each group of two stimuli in

Figure 1). The stimuli whose starting position and direction of pitch change were opposite were called "incongruent" (the right stimulus of each pair in Figure 1).

The stimuli can also be described in terms of their difference from the average pitch, with each stimulus being considered to have a small, medium or large "separation". The four sounds that were closest to the middle of the set had "small" separation (the four left-most stimuli in Figure 1). The four sounds that were highest and lowest relative to the middle of the pitch range were considered to have "large" separation, and the remaining four had "medium" separation. Note that separation was defined not in terms of onset pitch, but rather in terms of the average pitch for each stimulus.

Procedure. Subjects were told that they would hear sounds that would start either high in pitch or low in pitch, and which would become higher or lower in pitch. In one condition the task was to respond to whether the stimulus started high or started low, irrespective of the direction of pitch change. In the other condition, the task was to respond to whether the pitch became higher or lower, ignoring the onset pitch. In all cases, responses were keypresses of the " 6 " and " 9 " keys of the numeric keypad with the index and middle fingers of the right hand, respectively.

During the instruction phase, the subject heard each of the 12 stimulus sounds once. An accompanying message on the computer screen indicated, "These are the three tones that start high, and become higher in pitch," when the three high and congruent stimuli were played; the same method was used to present the remaining stimuli. Following presentation of the stimuli, the subject was assigned to one of two S-R assignments. Half of the subjects were instructed to respond using what was intended to be a spatially compatible S-R assignment, pressing the upper key (the "9" key) when the stimulus started high (or moved up in pitch), and pressing the lower key (the " 6 " key) when the stimulus started low (or moved lower). The other half of the subjects were instructed to respond using what was intended to be a spatially incompatible S-R
assignment (e.g., pressing the lower key when the stimulus started high in pitch, and pressing the upper key when the stimulus started low in pitch).

There were two sessions to the experiment. In each session subjects completed a block of 60 practice trials, then performed 2 blocks of 60 experimental trials, for a total of 180 trials. There were five repetitions of each of the twelve stimuli randomly presented within each block. Accuracy feedback was given on each trial, and overall accuracy was presented at the end of each block. Half of the subjects responded to the onset position for the first session (ignoring the direction of movement), and then responded to the direction of motion (ignoring onset position) in the second session. The other subjects responded first to direction, then responded to position in the second session.

At the conclusion of the second session, each subject was given a brief explanation of the purpose of the study and was dismissed from the experiment.

## Results

Practice trials were excluded from the analysis. In addition, responses faster than 100 ms or slower than 2000 ms (less than $1 \%$ of responses) were excluded. Mean correct RTs and mean accuracy were subjected to an analysis of variance (ANOVA) with order (respond to position then to direction vs. respond to direction then to position) and assignment (compatible S-R assignment vs. incompatible assignment) as betweensubjects factors, and cue dimension (position vs. direction), congruency (congruent vs. incongruent), separation (small, medium, or large stimulus separation) and block (Block 1 vs. 2) as within-subjects factors. An alpha level of .05 was used for all statistical tests.

RT results are plotted in Figure 2 as a function of cue dimension, separation and congruency.

FIGURE 2. Mean RT results of Experiment 1 as a function of cue dimension, congruency and separation.

The main effect of cue dimension was significant, reflecting that overall responses were faster [676 vs. $832 \mathrm{~ms} ; F(1,24)=13.00, p<.0014, M S E=314,462]$ and more accurate [ 94 vs. $87 \% ; F(1,24)=7.20, p<.0130, M S E=0.0576$ ] for position judgments than for direction judgments.

The main effect of congruency was significant for RT and for accuracy. Responding was faster [729 vs. $782 \mathrm{~ms} ; F(1,24)=11.80, p<.0022, M S E=37,457]$ and more accurate [94 vs. $88 \% ; F(1,24)=10.77, p<.0032, M S E=0.0268$ ] for congruent stimuli than for incongruent stimuli.

The Cue Dimension x Congruency interaction did not reach significance for RT, $F(1,24)=2.70, p<.11, M S E=16,051$, but it was significant for accuracy, $F(1,24)=$ 8.46, $p<.0077, M S E=0.0103$. When attending to position, responses to congruent stimuli were more accurate than responses to incongruent stimuli (96.0 vs. 93.4\%, respectively). When attending to direction, responses to congruent stimuli were also more accurate than to incongruent stimuli, but the congruency effect was larger for the direction judgments ( 92.7 vs. $82.9 \%$ for congruent and incongruent, respectively).

As separation increased, responses became significantly faster [mean RT $=793$ ms at the smallest separation, 744 ms at the medium separation and 731 ms at the largest separation; $F(2,48)=25.40, p<.0001, M S E=9,489]$. Accuracy also tended to be higher at the greater separations [from 89 to 93 to $91 \% ; F(2,48)=13.61, p>.001, M S E$ $=0.0051$ ).

The Cue Dimension x Separation interaction was significant, $F(2,48)=42.03, p$ $<.0001, M S E=7,780$. The pattern of faster responses for a greater stimulus separation was stronger for position judgments (mean $\mathrm{RT}=760$, 651 and 609 ms , for small, medium and large stimulus separation, respectively), than for direction judgments (mean RT = 827, 831 and 839 ms , for small, medium and large separations, respectively). The Congruency x Separation interaction was also significant, $F(2,48)=8.45, p<.0007$, $M S E=8,185$. As separation increased, RTs decreased for both congruent and incongruent stimuli, however the difference in RT between the smallest and largest separation was only 25 ms for incongruent stimuli, whereas it was 103 ms for congruent stimuli. Finally, the Cue Dimension x Congruency x Separation interaction was significant, $F(2,48)=13.41, p<.0001, M S E=6,778$. As shown in Figure 2, when attending to position (left side of Figure 2), responses to both congruent and incongruent stimuli were faster with an increased stimulus separation (congruent: 738, 637 and 591 ms ; incongruent: 783,665 and 627 ms for small, medium and large separations, respectively). However, when attending to direction, increased stimulus separation led to faster responding only for congruent stimuli (right side of Figure 2, open squares; 836, $792,772 \mathrm{~ms}$ ), whereas for incongruent stimuli, increased separation led to slower responding (filled circles; 820, 867 and 895 ms for small, medium and large separation, respectively).

The main effect of assignment was not significant for RTs, $F(1,24)<1$, nor did assignment appear in any significant interaction (see Appendix B for the complete ANOVA tables). In terms of accuracy, the main effect of assignment was also not
significant, $F(1,24)<1$, however assignment did appear in some significant higher-order interactions, as seen in Appendix B.

There was no main effect of order, $F(1,24)=2.14, p>.16, M S E=830,413$, nor were there any significant two-way interactions involving Order. The three-way Order x Cue Dimension x Separation interaction was significant for RT, $F(2,48)=7.05, p<$ $.0021, M S E=7,780$. Regardless of the order of conditions, position responses were faster for larger separations (position then direction order: mean RT $=659,571$ and 547 ms for small, medium and large separation, respectively; direction then position order: mean $\mathrm{RT}=862,731$ and 669 ms ). For direction responses, however, responding first to position then to direction (Order 1) resulted in little change to direction responses with increased separation (mean $\mathrm{RT}=820,795$ and 818 ms for small, medium and large separation). Responding to direction first, then to position (Order 2) resulted in an increase in RTs with greater separation (mean $\mathrm{RT}=835,867,861 \mathrm{~ms}$ for small, medium and large separation).

The significant main effect of block on accuracy showed that performance improved with practice, as mean accuracy increased from $90 \%$ in Block 1 to $92 \%$ in Block 2, $F(1,24)=7.19, p<.0131, M S E=0.0028$, while RT remained unchanged [756 vs. $758 \mathrm{~ms}, F(1,24)<1]$. This reflects the typical improvement in performance that results from practice on a speeded-reaction task.

## Discussion

As predicted, the dimensions of pitch and pitch change interacted, so that responses were almost always faster when the direction of pitch change matched the onset pitch position (i.e., for congruent stimuli). This parallels the results of studies using static auditory stimuli, as well as both static and dynamic visual stimuli. It is important to note that dynamic auditory stimuli (i.e., changing pitches) seem to behave in some ways similar to dynamic visual stimuli. That is, the dimension of position influences the
perception of, and responding to, direction, and vice versa. This makes it clear that both pitch and pitch change need to be considered when designing auditory stimuli and auditory displays, but it also provides a visual analogy to help designers remember and understand the interaction of two stimulus dimensions.

Overall, in this experiment responding to pitch position was faster than responding to direction of pitch change. This is likely due, at least in part, to the fact that responding to direction required waiting until the pitch changed (i.e., a minimum of 25 ms , the amount of time that the stimulus remained at the onset pitch). However, that does not explain the responses to direction being more than 150 ms (i.e., more than half the duration of the stimulus) slower on average. It is possible that pitch is processed in some way differently from direction of pitch change, which could lead to faster responses. Subjects may also have more pre-experimental practice with pitch judgments than with pitch-change judgments, resulting in what amounts to a long-term practice effect. Alternatively, the dimension of pitch may have been simply more effective at making the stimuli more or less discriminable. At this point it is not possible to know conclusively why pitch responses were faster, but the use of twelve stimuli was intended to help balance the stimulus set so that any discriminability issues would be minor in comparison to the effects of practice or differential processing speeds.

It is interesting to note how cue dimension, separation and congruency interacted (see Figure 2). Position judgments were faster for congruent stimuli than for incongruent stimuli, but for both congruent and incongruent stimuli the greater the separation, the faster the responses to position (left panel of Figure 2). It makes sense that more separated pitches would result in faster responses when pitch is the cue dimension, since separation can also be considered a measure of stimulus discriminability for pitch. Within the stimulus set, it should be easiest to respond to stimuli that are more discriminable. The slowdown due to incongruent direction information is fairly constant with increased separation, suggesting that direction information has a uniform effect on
position judgments for all of the stimuli. This tends to confirm that a change in perceived pitch (which was equal at each separation), and not in absolute frequency (which varied from 185 to 927 Hz ), is processed when judging direction.

When attending to direction, a different pattern of results was obtained. Congruent stimuli were, on the whole, still faster than incongruent stimuli, but there was little gain in performance with increased separation (right panel of Figure 2, open squares). That is, direction judgments seemed unaided by greater separation when the pitch and the direction matched. When the pitch was incongruent with the direction of pitch change, however, greater separation meant much slower responses to direction. Hence, it appears that the further the pitches were from the middle of the pitch space, the more salient pitch became, and the greater its interference with direction judgments. This was especially true for the largest level of separation. When separation was small, it was apparently harder to discriminate the different pitches, making pitch less salient. In this case it was apparently easier to ignore the irrelevant position information, as indicated by better performance on the direction judgment.

Based on these results, it seems reasonable to conclude that if pitch is the dimension of a dynamic auditory message to which an operator must attend, there will always be some intrusion of the direction information. Selective attention is not perfect. However, a greater separation in the onset of pitches will mean better performance on the task, with no increased interference from direction information as a result. If pitch change is the important dimension, then in terms of performance on a selective listening task there is little to be gained with increased pitch separation in the case of congruent stimuli, and much to be lost in the case of incongruent stimuli. Hence, to reduce the deleterious effects of the irrelevant pitch information, an auditory display designer can restrict the range over which stimulus onsets may vary for a given task.

The lack of any assignment effect in the present experiment is surprising. If pitch really were treated by listeners as having a spatial aspect (e.g., Mudd, 1963), then there
should have been spatial compatibility effects resulting from the different assignments of stimuli to responses. If there really is no effect of assigning upper keypresses to highpitched rather than low-pitched sounds, and vice-versa for lower keypresses, that would suggest that pitch is not really spatial, or at least that the pitch space is not comparable to the response space in this case.

There may, however, be other reasons for the lack of an assignment effect. If, for example, the response set were not spatial, or even if the response set were arranged in a spatial, but non-vertical way, then a vertically oriented pitch space might not interact with the responses to cause spatial compatibility effects. That is, if the responses were leftright, pitch could be coded as up-down, such that a detectable compatibility effect might not be present. Recent evidence (Lippa, 1996) indicates that the arrangement of responses must be assessed relative to the hand of the subject, and not relative to the subject's body or the rest of the apparatus. Lippa found that for visual stimuli certain types of spatial S-R compatibility effects were found only if the relevant stimulus dimension (e.g., vertical position of lights) was aligned parallel to the response set (e.g., two vertically arranged buttons), with the alignment of the responses being determined relative to the hand, not relative to the rest of the body. Although the response keys in the present experiment (the " 6 " and " 9 " keys on the numeric keypad) were chosen so that the " 9 " key would be higher than the " 6 " key, the subjects may not have treated them as being in a truly vertical arrangement. The bent arm position that was required to put the right index finger on the " 6 " key and the second finger on the " 9 " key of the numeric keypad would result in a left-right arrangement of the keys, relative to the hand. In addition, while the " 9 " key is physically located higher than the " 6 " key, it is only slightly so, and in any case, it is not really "higher" relative to the whole hand. Thus, considering Lippa's results, a more vertical response set might correspond more closely to the pitch space, and result in spatial compatibility effects. Such a finding would provide evidence that pitch really is treated by listeners in a spatial way.

In addition to making the vertical alignment of the response set more salient, it may be necessary to increase the salience or "separation" of the responses. After all, the separation of the stimuli in the pitch space affected responding, so greater or lesser separation of the responses may have a similar effect. Experiment 2 thus used a modified response set to address these concerns.

## EXPERIMENT 2

## Method

Experiment 2 was identical to Experiment 1, except for the following: First, the response apparatus was changed to create a truly vertical response set, and two different sets of response buttons, differing only in their separation relative to each other, were used. Second, due to suspected differential carry-over effects in Experiment 1, cue dimension was changed to a between-subjects variable.

Participants. Sixty-four new subjects from the same subject pool as in Experiment 1 participated in this experiment. None of the subjects had participated in any of the previous pilot studies nor in Experiment 1.

Apparatus. The computer apparatus that controlled the experiment and presented the sound stimuli was identical to that used in Experiment 1, except that subjects now responded by pressing the buttons of a five-button PST Serial Response Box (a response device produced by Psychological Software Tools, specifically for use with the MEL experiment-control software system), which was supported on a wooden stand as illustrated in Figure 3. The response buttons were arranged in a single vertically oriented row, although the whole response box was inclined away from the subject at a $10^{\circ}$ angle to allow the subject to press the buttons with the fleshy part of the fingertip, rather than the tip of the fingernail. For the purposes of explanation, the buttons will be referred to here in numerical order, starting from the bottom. Thus, the lowest button is "Button 1"
and the top button is "Button 5" (they were not so labeled for the subjects). Subjects rested their right wrist on a $5-\mathrm{cm}$ thick piece of foam placed on the table between the subject and the response box. This maintained a comfortable arm and hand position, while allowing for unimpeded movement to any of the response buttons. All responses were performed with the right index finger. There were two types of responses: the "near" responses, which involved moving from the "home" button to either Button 2 or Button 4 (see Figure 3), and the "far" responses, which involved moving from the "home" button to either Button 1 or Button 5.

FIGURE 3. Schematic diagram of the apparatus used in Experiment 2. Panel A shows the start of a trial. Panel B shows the subject pressing the middle "home" button, while waiting for the stimulus sound. Panel C shows the response apparatus just after a correct "far" response has been made.

Stimuli. The stimuli were identical to those used in Experiment 1.
Procedure. The trial procedure differed from Experiment 1 only as follows: At the start of each trial, the light beside the middle button (Button 3) of the response box came on (see Panel A of Figure 3). The subject began the trial by pressing down and holding this "home" button, and waiting for the stimulus sound. When the home button was pressed and held, the middle light was turned off and the lights were turned on beside Buttons 2 and 4 (in the near-response condition), or beside Buttons 1 and 5 (in the
far-response condition), as a reminder of the valid responses for that trial (Panel B of Figure 3). The subject waited for the stimulus sound, then, as quickly as possible, moved the index finger off the home button and pressed one of the valid response buttons. If the subject pressed the correct button, the light beside it stayed on (recall that it was already on as a reminder to the subject), the other lights were turned off and the message, "Correct response" appeared on the computer screen (see Panel C of Figure 3). If the subject pressed an incorrect button (or made no response within 3 s ), all the response box lights came on and "Wrong response!" appeared on the computer screen. Finally, if the subject released the home button before the stimulus started, the message, "You moved too soon!" appeared on the computer screen.

The block structure was the same as in Experiment 1, with three blocks of 60 trials in each session of the experiment. Instead of responding to a different cue dimension in each session, as was the case in Experiment 1, the subjects now responded to the same cue dimension, either position or direction, for the entire experiment. In one session subjects now used the "near" buttons to respond and in the other session they used the "far" buttons. This order of response types was counterbalanced across subjects.

As in Experiment 1, half of the subjects responded throughout with a compatible response assignment, whereas the other half of the subjects responded throughout with an incompatible assignment.

## Results

The practice trials and trials on which responses were less than 100 ms or greater than 3000 ms (less than $0.5 \%$ of trials) were excluded from the analysis.

Mean correct RTs and mean accuracy were subjected to separate ANOVAs, with cue dimension (position vs. direction), assignment (compatible vs. incompatible) and order (near response condition, then far response condition vs. far then near) as betweensubjects factors. Response type (near vs. far), congruency (congruent vs. incongruent),
separation (small, medium or large) and block (Block 1 or 2) were within-subjects factors. Total RT (the time from the onset of the sound until the response button-press) and accuracy were the primary dependent measures, as before. In addition, the time required to release the home button ("lift time"), and the time required to move to the response button ("movement time") were analyzed separately (see Appendix C for the ANOVA tables). Lift and movement times will be discussed only where the results of the analyses differ from the total RT results.

The analysis of the whole experiment showed significant effects of the order in which the response types were used. For that reason, the data from the first session for each subject were also analyzed separately (such that only the data from the first response type that each subject used were included). The results of the Session 1 analysis are presented following the report of the complete experiment.

FIGURE 4. Mean RT results of Experiment 2 as a function of cue dimension, congruency and separation.

ANOVA Results for the Complete Experiment. Mean correct RTs, as a function of cue dimension, separation and congruency, are presented in Figure 4. The main effect of
cue dimension was significant, reflecting that overall responses were faster for position judgments than for direction judgments [628 vs. 784 ms , respectively; $F(1,56)=12.14, p$ $<.0010, M S E=770,198]$. The main effect of cue dimension was not significant for accuracy, $F(1,56)=1.18, p<.2818, M S E=0.086$.

The significant main effect of congruency for both RT, $F(1,56)=47.48, p<$ $.0001, M S E=30,777$, and accuracy, $F(1,56)=16.85, p<.0001, M S E=0.047$, reflects the fact that responses to congruent stimuli were faster ( 676 vs .737 ms ) and more accurate ( $96.4 \mathrm{vs} .91 .1 \%$ ) than responses to incongruent stimuli.

The Cue Dimension x Congruency interaction also was significant for RT, $F(1$, $56)=10.25, p<.0023, M S E=30,777$, but not for accuracy, $F(1,56)=3.23, p<.0777$, $M S E=0.047$. When attending to position, responses to congruent stimuli were 33 ms faster than responses to incongruent stimuli ( 612 vs .645 ms ). When attending to direction, however, the difference between responses to congruent and incongruent stimuli was 91 ms ( 739 vs .830 ms for congruent and incongruent, respectively).

As separation increased, RT decreased significantly [mean RT $=728 \mathrm{~ms}$ at the smallest separation, 696 at the medium separation and 695 ms at the largest separation, $F(2,112)=16.69, p<.0001, M S E=111,141]$. Accuracy also tended to be higher at the greater separations [accuracy $=91.9,95.7$ and $94.8 \%$ for small, medium and large separations, respectively; $F(2,112)=24.55, p<.0001, M S E=0.008]$.

The Cue Dimension x Separation interaction was significant for RT, $F(2,112)=$ $62.59, p<.0001, M S E=11,141$. When position was the relevant cue dimension, RTs decreased with increased separation (691, 610 and 585 ms for small, medium and large separations, respectively). However, when attending to direction, RTs tended to be slower with increased separation (766, 781 and 806 ms for small, medium and large separations, respectively). The Cue Dimension x Separation interaction was also significant for accuracy, $F(2,112)=82.39, p<.0001, M S E=0.008$. When position was the relevant cue dimension, accuracy increased with increasing separation (accuracy $=$
88.6, 97.9 and $98.3 \%$ for small, medium and large separations, respectively). When direction was the relevant cue dimension, however, accuracy decreased with greater separation (accuracy $=95.2,93.5$ and $91.3 \%$ for small, medium and large separations, respectively), thus showing the same pattern of performance as the RT results.

The Congruency x Separation interaction was significant for both RT, $F(2,112)=$ $19.08, p<.0001, M S E=14,754$, and accuracy, $F(2,112)=5.71, p<.0044, M S E=0.005$. For congruent stimuli, RTs decreased and accuracy increased with increasing separation (mean $\mathrm{RT}=721,665$ and 641 ms ; accuracy $=93.1,97.5$ and $98.6 \%$ for small, medium and large separations, respectively). However, for incongruent stimuli, RTs tended to increase from 736 ms at the smallest separation to 750 ms at the largest separation, while accuracy tended to increase slightly from $90.7 \%$ at the smallest separation to $91.0 \%$ at the largest separation.

Finally, the Cue Dimension x Congruency x Separation interaction was significant for RT, $F(2,112)=30.54, p<.0001, M S E=14,754$, and for accuracy, $F(2$, $112)=20.06, p<.0001, M S E=0.016$. As seen in Figure 4, for subjects who attended to position throughout the experiment (left side of Figure 4), responses to both congruent and incongruent stimuli were faster with increased stimulus separation (congruent: mean $\mathrm{RT}=666,597$ and 573 ms ; incongruent: mean $\mathrm{RT}=715,622,598 \mathrm{~ms}$ for small, medium and large separations, respectively). Accuracy for these responses followed the same pattern, in that responses to both congruent and incongruent stimuli were more accurate with increased separation (congruent: accuracy $=91.4,98.6$ and 98.6\%; incongruent: accuracy $=85.9,97.1$ and $98.0 \%$ for small, medium and large separations, respectively). However, when direction was the relevant dimension (right side of Figure 4), RTs to congruent stimuli decreased with increased separation (mean $\mathrm{RT}=775,734$ and 709 ms ), whereas responses to incongruent stimuli showed the opposite pattern, namely a pronounced slowing with increased stimulus separation (mean RT $=757,830$ and 902 ms for small, medium and large separations, respectively). The accuracy results again
followed the same pattern as the RT results, as direction responses to congruent stimuli became more accurate with greater separation (accuracy $=94.8,96.4$ and $98.5 \%$ for small, medium and large separation) whereas direction responses to incongruent stimuli became less accurate with increased separation (95.5, 90.5 and $84.1 \%$ for small, medium and large separations, respectively). The pattern of results for this three-way Cue Dimension x Congruency x Separation interaction is identical to the pattern found in Experiment 1.

FIGURE 5. Mean RT results in Experiment 2 as a function of assignment, response type and order.

The main effect of assignment was not significant for RT, $F(1,56)=1.85, p<$ $.18, M S E=770,198$, nor for accuracy, $F(1,56)=1.01, p<.32, M S E=0.086$, however, assignment figured in a three-way interaction, as discussed below.

The significant main effect of response type for RT reflects that overall responding to the near buttons was significantly faster than responding to the far buttons [677 vs. $736 ; F(1,56)=43.06, p<.0001, M S E=30,480$ ]. The main effect of response type was not significant for accuracy, $F(1,56)=3.62, p<.0623, M S E=0.015$. The

Assignment x Response Type interaction was not significant for RT, $F(1,56)=2.78, p<$ .10, $M S E=30,480$, nor for accuracy, $F(1,56)<1$.

The main effect of order was not significant for RT, $F(1,56)<1$, nor for accuracy, $F(1,56)=1.65, p<.20, M S E=0.086$. The Assignment x Order interaction was not significant for RT, $F(1,56)=1.56, p<.22, M S E=770,198$, nor for accuracy, $F(1,56)=1.81, p<.18, M S E=0.086$. There was, however, a significant Response Type x Order interaction for RT, $F(1,56)=22.66, p<.0001, M S E=30,480$, and for accuracy, $F(1,56)=13.48, p<.0005, M S E=0.015$, but this effect was qualified by several significant three-way interactions. The Assignment x Response Type x Order interaction was significant for RT, $F(1,56)=7.03, p<.0104, M S E=30,480$ (see Figure 5), but not significant for accuracy, $F(1,56)=2.19, p<.14, M S E=0.015$. For the compatible assignment (left side of Figure 5), both orders resulted in near responses being faster than far responses (near-then-far order: near mean $\mathrm{RT}=658$, far mean $\mathrm{RT}=713 \mathrm{~ms}$; far-thennear order: near mean $\mathrm{RT}=621$, far mean $\mathrm{RT}=712 \mathrm{~ms}$ ), which is most likely due to the greater distance traveled by the finger to make the far responses. For subjects who used an incompatible S-R assignment (right side of Figure 5), the far-then-near order also resulted in the near responses being faster than the far responses (upper arrow: near mean RT $=729$, far mean $R T=838 \mathrm{~ms}$ ). However, the near-then-far order with an incompatible S-R assignment resulted in the opposite pattern of results, namely the near responses being slower than the far responses (lower arrow: near mean $\mathrm{RT}=702$, far mean $\mathrm{RT}=679 \mathrm{~ms})$.

There was some evidence of a compatibility effect when making far responses as the first response type (the right-most filled circle in each panel of Figure 5), as compatible responses were numerically faster than incompatible responses (mean $\mathrm{RT}=$ 712 vs. 838 ms for compatible and incompatible responses, respectively), however this difference did not reach significance, $t(1,30)=1.63, p>.10]$.

FIGURE 6. Mean RT results in Experiment 2 as a function of cue dimension, response type and order.

The Cue Dimension x Response Type x Order interaction was significant for RT, $F(1,56)=13.50, p<.0005$, MSE $=30,480$, but not for accuracy, $F(1,56)=3.64, p<$ $.0617, M S E=0.015$. The pattern of RTs (shown in Figure 6) was very similar to the pattern just described for the Assignment x Response Type x Order interaction. For the subjects who attended to position (left side of Figure 6), near responses were faster in both the near-then-far order (near mean $\mathrm{RT}=601$, far mean $\mathrm{RT}=639 \mathrm{~ms}$ ) and the far-then-near order (near mean $\mathrm{RT}=609$, far mean $\mathrm{RT}=666 \mathrm{~ms}$ ). For subjects who attended to direction of pitch change (right side of Figure 6), the far-then-near order resulted in faster responding to the near buttons (near mean $\mathrm{RT}=741$, far mean $\mathrm{RT}=895$ ms ), but in the near-then-far order the far responses were slightly faster than the near responses (near mean $\mathrm{RT}=759$, far mean $\mathrm{RT}=753 \mathrm{~ms}$ ).

FIGURE 7. Mean RT results in Experiment 2 as a function of congruency, response type and order.

The Congruency x Response Type x Order interaction was also significant for both RT, $F(1,56)=4.85, p<.0318, M S E=7,959$, and accuracy, $F(1,56)=11.98, p<$ $.0010, M S E=0.006$, and the pattern of RT results (shown in Figure 7) was very similar to that of the two interactions just described. For responses to congruent stimuli (left side of Figure 7), both orders resulted in the near responses being faster than the far responses (near-then-far order: near mean $\mathrm{RT}=650$, far mean $\mathrm{RT}=677 \mathrm{~ms}$; far-then-near order: near mean $\mathrm{RT}=642$, far mean $\mathrm{RT}=734 \mathrm{~ms}$ ). For responses to incongruent stimuli (right side of Figure 7), the far-then-near order resulted in much faster responding to the near buttons (near mean $\mathrm{RT}=708$, far mean $\mathrm{RT}=817 \mathrm{~ms}$ ), and in the near-then-far order the near responses were also slightly faster than the far responses (near mean RT $=710$, far mean $\mathrm{RT}=715 \mathrm{~ms}$ ). In terms of accuracy, for responses to congruent stimuli, both orders resulted in the near responses being less accurate than the far responses (near-thenfar order: near accuracy $=96.1$, far accuracy $=98.2 \%$; far-then-near order: near accuracy $=95.6$, far accuracy $=95.7 \%$ ). Thus, there seems to be a speed-accuracy tradeoff for these responses. For responses to incongruent stimuli, in the far-then-near order near
responses were more accurate than far responses (near accuracy $=91.9$, far accuracy $=$ 89.5\%), whereas in the near-then-far order near responses were less accurate than far responses (near accuracy $=90.6$, far accuracy $=95.5 \%$ ). This pattern of results for accuracy again suggests a speed-accuracy tradeoff in performance.

The main effect of block on total RTs was significant, as RTs decreased from Block 1 to Block 2 [ 717 vs. $696 \mathrm{~ms}, F(1,24)=5.77, p<.0197, M S E=28,277$ ] and overall accuracy increased [93.6 to $94.7 \%, F(1,24)=7.08, p<.0102, M S E=0.0061]$. The main effect of block was not significant for movement time, $F<1$, but it was significant for lift time, suggesting that performance did not improve due to faster movements, but rather due to faster planning or faster initiation of the action [359 vs. 344 ms for lift time, in Blocks 2 and 3, respectively; $F(1,56)=6.03, p<.0172, M S E=$ $15,799]$.

ANOVA Results for the First Session. Since there were effects of the order in which the near and far responses were used, it may have been the case that compatibility effects were present in the initial session of the experiment, but the change of response mode obscured the effect. Therefore, the data from the first session for each subject (thus making response type a between-subjects factor) were analyzed in a separate ANOVA. Other than the omission of order as a factor and the treatment of response type as a between-subjects factor, the analysis was identical to the ANOVAs performed on the complete experiment.

The overall pattern of results for the first session was very similar to the pattern of results for the complete experiment (see Appendix D for the ANOVA tables). In the following, accuracy results will only be reported where they differ from the RT results. The main effects and interactions of cue dimension, congruency and separation followed the identical pattern as in the analysis of the whole experiment, so they will not be discussed further here.

For total RT, the main effect of assignment was only marginally significant, $F(1$, $56)=2.99, p<.09, M S E=458,928$, and it was not significant for accuracy, $F(1,56)=$ 1.67, $p<.20, M S E=0.068$. Assignment did not figure in any significant interactions for RT. The main effect of assignment was significant for movement time, $F(1,56)=12.02$, $p<.0010, M S E=277,197$, as the movement part of compatible responses was considerably faster than the movement part of incompatible responses (mean movement time $=299$ vs. 431 ms for compatible and incompatible responses, respectively). This movement time result suggests the presence of a compatibility effect. However, for lift time, the main effect of assignment was not significant, $F(1,56)=1.83, p<.18, M S E=$ 233,641, but, numerically at least, the lift part of compatible responses was slower than the lift part of incompatible responses (mean lift time $=386 \mathrm{vs} .339 \mathrm{~ms}$ for compatible and incompatible responses, respectively), if anything suggesting a reverse compatibility effect for lift time.

For RT there was no significant effect of response type, nor did response type figure in any significant interactions. The main effect of response type was significant for movement time, with near movements faster than far movements [mean movement time $=322$ vs. 407 ms for near and far, respectively; $F(1,56)=5.03, p<.0289, M S E=$ 277,197]. None of the interactions of assignment or response type with congruency, with separation or with cue dimension was significant for movement time. For lift time, however, the main effect of assignment, already described, was qualified by the significant Assignment $x$ Congruency interaction, $F(1,56)=4.59, p<.0364$, MSE $=$ 3,439 (see Figure 8). The lift part of compatible responses to congruent stimuli was faster than the lift part of responses to incongruent stimuli (mean lift time $=372 \mathrm{vs} .400$ ms for congruent and incongruent stimuli, respectively). A similar pattern resulted for the lift part of incompatible responses (bottom line, Figure 8), where reactions to congruent stimuli were slightly faster than reactions to incongruent stimuli (mean lift time $=334$ vs. 344 ms for congruent and incongruent stimuli, respectively). Note that in
all cases the incompatible lift times were faster than the lift times for compatible responses.

FIGURE 8. Mean lift time results for the first session in Experiment 2 as a function of assignment and congruency.

For accuracy of the total responses, in addition to the results already described the Assignment x Cue Dimension x Response Type interaction reached significance, $F(1,56)$ $=4.02, p<.0497$, MSE $=0.0684$ (see Figure 9). When responding with a compatible assignment (left side of Figure 9), the accuracy of position responses was higher for near responses than for far responses ( $95.5 \mathrm{vs} .92 .8 \%$, respectively), whereas the accuracy of direction responses was considerably lower for near responses than for far responses ( 86.3 vs. $92.4 \%$, respectively). When responding with an incompatible assignment (right side of Figure 9), the accuracy of position responses was almost identical for near and for far response types ( 94.6 vs. $94.7 \%$ for near and far responses, respectively), and accuracy
for direction responses was higher for near than for far responses (96.9 vs. $90.1 \%$, respectively).

FIGURE 9. Mean accuracy results for the first session in Experiment 2 as a function of assignment, cue dimension and response type.

## Discussion

The pattern of results with respect to cue dimension, congruency and separation was identical to Experiment 1, which is not surprising since the stimuli were not changed from Experiment 1 to Experiment 2. It seems clear that the two dimensions of pitch and pitch change influence the perception of and responding to one another. The only change with regard to any of the stimulus factors from Experiment 1 to Experiment 2 was that subjects only responded to one or the other of the cue dimensions; this had no effect on the overall pattern of results.

Despite efforts to create a truly vertical response set, there were only hints of the S-R compatibility effects that were expected to result from the interaction of the stimulus set and the response set, had pitch been treated spatially. The main effect of assignment for movement times might seem to indicate a compatibility effect arising from the
interaction of pitch and the response set. However, the hint of a reverse compatibility effect for lift times makes it unclear how to interpret the main effect of assignment for movement times. Much of the previous research on spatial compatibility effects has shown that these effects arise during the response selection stage of processing, rather than during the response production or response completion stage (e.g., Proctor \& Reeve, 1990). In the present experiment, the response selection stage should precede the movement, and therefore compatibility effects would have their effects more on lift times than on movement times. However, subjects may have lifted their finger before or during response selection, thereby mixing the response selection and response production stages of processing into the movement time.

Perhaps more could be done to create an even more compellingly vertical response set, but it is difficult to imagine how. It is possible that a different sort of response action, such as the deflection of a joystick would result in different S-R effects, but it appears more likely that a true absence of an assignment effect for changing pitches is not the result of quirks in the response set. S-R compatibility effects are so strong and prevalent in such a range of other tasks (e.g., Proctor \& Reeve, 1990) that it is more likely due to the nature of the task or the stimuli that strong compatibility effects were not obtained. Possible accounts for the observed lack of compatibility effects will be considered in the General Discussion.

The results of Experiment 2 showed that the response type (near or far responses) and the order in which the subject used those response types, interacted with assignment, cue dimension and congruency. Although the stimulus dimensions and S-R assignments were the main focus in Experiment 2, these order effects are also interesting. In terms of response type and the order in which the two response types are used, there are two competing factors. First, because the subject completed a large number of trials with one response type ( 180 trials, including practice), the second response type should result in faster RTs due to practice with the task. If the second response type is to the farther
buttons, this speed-up should help to overcome the longer RTs associated with the greater movement distances. If the second response type is to the nearer buttons, then the speedup due to practice should add to the speed-up due to the shorter response distance, resulting in a considerably faster response than in the first (far) response type. This overall speed-up also depends on other factors in the task, such as the assignment of stimuli to responses. In the case of the compatible assignment (left side of Figure 5), it seems that the longer movement time is not overcome by the increased speed due to practice. However, in the incompatible assignment (right side of Figure 5, bottom arrow), the practice effects seem to be more beneficial than the increased distance is detrimental. A similar pattern is observed for the interactions of response type and order with cue dimension and with congruency. When the cue dimension was position (in the Cue Dimension x Response Type x Order interaction) or when responses were to congruent stimuli (in the Congruency x Response Type x Order interaction), the far responses were slower than the near responses, but the effects of practice helped to reduce the difference in RTs between near and far responses. However, when the cue dimension was direction (in the Cue Dimension x Response Type x Order interaction), or when responses were to incongruent stimuli (in the Congruency x Response Type x Order interaction), when far responses are performed second, RTs were comparable to those for near responses. That is, the speed-up in RT that results from practice was greater than the slowing effect of moving farther to respond.

In all of the interactions involving response type, order and a third factor, it was the more difficult task (i.e., the incompatible responses, the direction responses and the responses to incongruent stimuli), that showed evidence of practice effects overcoming the slowdown due to the farther responses. This similarity seems to indicate that the best way to train someone to perform these sorts of tasks depends both on how much effect practice has on the task, and the nature of the final task. For example, if the task involves compatible responses and the desired final motion is relatively far from the home button,
it does not much matter whether the subject first practices with a near response, or the far response is performed without prior practice (only a 1-ms difference in the present experiment). However, if the final response is incompatible, then training with a near response will result in positive transfer to a far response.

## GENERAL DISCUSSION

Designing the displays and the controls through which an operator interacts with a system requires an understanding of how the stimuli in the displays are perceived and how the information transmitted to the operator is translated into control actions. As auditory displays become more common it is increasingly important to understand the perception of complex and dynamic auditory stimuli and how the information contained in the various dimensions of these stimuli influences performance.

The research presented here examined the manner in which the auditory dimensions of pitch and pitch change interact to influence performance in a selective listening task that is typical of what might be required when using an auditory display. In particular, this research investigated congruency and compatibility effects with dynamic auditory stimuli, namely tones that become higher and lower in pitch.

One major question of interest here was whether the auditory dimensions of pitch and pitch change interact to influence responding to either dimension. The results of both Experiments 1 and 2 showed that responding to the onset pitch of a sound is faster than responding to the direction of pitch change of that sound. However, subjects were unable to listen to either aspect of the sounds in a completely selective manner, in that the direction of pitch change influenced pitch judgments, and vice versa. In other words, there appeared to be cross-talk (e.g., Melara \& O'Brien, 1990) between the two stimulus
dimensions, such that each dimension influenced either the perceptual or judgment processes underlying responses to the other dimension.

The intrusion of the information of one dimension onto judgments regarding the other dimension was not symmetrical in the present experiments, in that pitch information had a greater influence on responses to direction of pitch change than direction information had on pitch judgments. However, in both cases, when the two dimensions provided congruent information (e.g., a high pitch also became higher in pitch) responses were faster than if the two dimensions provided incongruent information (e.g., a high pitch became lower in pitch).

It was also observed that the congruency effect was fairly uniform for pitch judgments across the range of stimuli. However, for pitch-change judgments, responses to the stimuli which were more extreme in pitch (as compared to the average pitch of the set) were more influenced by irrelevant pitch information. Thus, these results suggest that for the design of auditory displays, the nature of the task should be considered in deciding upon the range of stimuli to use. In particular, if pitch is the dimension of interest, then the stimulus set should be widely separated in pitch. If, however, onset pitch is to be ignored, and it is the change in pitch that is to be attended, the stimuli should all be in a smaller pitch range, to lessen the effects of the intrusion of irrelevant pitch information onto direction judgments.

If pitch is treated by listeners in a spatial way, as is suggested by the common use of spatial descriptors for pitch in everyday language and by previous findings of S-R compatibility and Simon effects involving pitch (Mudd, 1963; Simon \& Rudell, 1967), spatial S-R compatibility effects should be apparent when pitch is assigned to spatial responses. For this reason, the overall lack of strong S-R compatibility effects in both Experiments 1 and 2 was surprising. It should be noted that previous demonstrations of a Simon effect with pitch (Simon \& Rudell, 1967) were conducted in a task in which the sounds were presented from speakers that were located above or below a reference point.

It may be that the use of separate speaker locations has the effect of making the quasispatial aspect of pitch more salient. In a similar way, the pegboard responses in Mudd's (1963) study actually required the subject to indicate a spatial correspondence between two pitches, which certainly would increase the salience of the spatial aspect of pitch. In the present work, however, all sounds were presented from one speaker, which perhaps minimized the spatial quality of the stimuli. Further work is underway to determine whether the use of one versus two speakers is the reason for the different outcomes with respect to effects of S-R assignments.

If compatibility effects are present between pitch and vertically arranged responses, but are simply difficult to produce, they are of limited interest. However, as mentioned, other studies have found some spatial compatibility effects with simple pitches. Perhaps, then, it is something particular about dynamic auditory stimuli that causes the lack of S-R compatibility effects. For example, perhaps the changes in pitch cause the listener to focus more on the relative auditory aspects of the pitches, and process them in a more "sound-specific" way. Pitch and pitch change would both be treated within the same conceptual framework (i.e., they would still be in the same conceptual "space", in the same way that hue and saturation are both considered part of the same "color space"), but this would no longer be tied so closely to the positioning of the sounds in the physical world. There is no a priori reason to think that the information extracted by using this more focused strategy of listening to pitch would interact with the physical arrangement of responses (or with any non-pitch dimension within the same stimulus or an attribute of another stimulus). The resulting dissociation of pitch and vertical position could well result in the sounds being treated as less "spatial" in the sense of vertical position. This in turn would result in the lack of a spatial compatibility effect.

The default mode of auditory perception may be to listen generally, or holistically to a sound, as could be the case in the present experiments, but the requirements of the task may cause the subject to change this listening strategy (even without the intention to
do so). This general line of reasoning is supported by the findings of Bregman and Walker (1993), where subjects were presented with brief "chirps" made up of three concurrent pitch components that were not unlike the stimuli used in the present experiments, and then asked to perform either holistic or analytic listening tasks. While the results of their work indicated that it was quite possible to attend selectively to one of the three components of the stimuli, Bregman and Walker found that the default mode of listening for most people was to attend to the whole sound, rather than to just one element within it. That is, once the sound was perceived as a unified whole, it was difficult to listen analytically again. Neither Bregman and Walker's study nor the present research specifically examined whether the analytic listening strategy is learned or developed. It may be that people who listen more "holistically" would treat pitch in a more spatial way, and thus be more likely to exhibit spatial compatibility effects when responding to pitch with a vertical response set. This possible influence of listening strategy on compatibility effects has yet to be studied.

Although the dimension of pitch is often referred to in spatial terms in "western" culture, there are cultures that do not refer to pitch in the same terms used to describe vertical position. Kubik (1975) points out that in many Bantu languages the words "small" and "large" are used to describe what English speakers call "high" and "low" pitches, respectively. This characterization presumably comes from the size of the object that typically produces a given class of sounds. Such use of different descriptors for pitch provides more support for the theory that treating pitch as a spatial concept is learned, and possibly cultural. Further research in the area of dynamic auditory stimuli as used to guide speeded responses should examine whether there are different types of listening strategies, and possibly different types of listeners, which may result in differing performance on tasks involving selective listening and rapid responding.

```
APPENDIX A: Stimulus Parameters
```

The auditory stimuli were 250 -ms pitch glides composed of ten intermediate steps. The initial and final frequencies are presented in Table A-1. The changes to the stimuli were equal in terms of log-frequency, so that the perceived pitch change should be approximately equal for all stimuli (Moore, 1989).

The frequencies were calculated with the following equation:

$$
\begin{equation*}
f=10^{\mathrm{N}} \tag{Eq.A.1}
\end{equation*}
$$

where $f$ is the frequency of the sound, and N is the "exponent" listed in Table A-1. For example, Stimulus 3 has the onset frequency of: $f=10^{(3)}=1000 \mathrm{~Hz}$.
